

[Frame 41] Where this bearer came from. This diagram opens on a Radio Link Control (RLC) entity that did not exist a fraction of a second earlier. Frame 38 of the capture — on the signaling bearer, so it is not on this diagram — carried an RRC Reconfiguration that added **Data Radio Bearer (DRB) 1** on logical-channel ID 4 and configured its RLC in Acknowledged Mode with:

- sn-FieldLength – size18, in both directions
- t-PollRetransmit – ms80 (uplink)
- pollPDU / pollByte – p32768 / kB750 (uplink)
- t-Reassembly – ms80 (downlink)
- t-StatusProhibit – ms30 (downlink)

Everything you are about to read follows from those five lines, starting with this frame.

The first PDU. This is the first protocol data unit (PDU) the new entity puts on the air. SN=0, and the sequence-number field is **18 bits wide** – the packet trace confirms bearer type DRB, bearer id 1, sequence-number length 18. RLC numbers *SDUs* – service data units, the PDCP packets handed down to it – not bytes and not transmissions, and a new entity starts that count at zero with nothing in its retransmission buffer. SI = "all bytes of an RLC SDU" (the 2-bit Segmentation Info field, value 0) says this PDCP packet fitted in one PDU, and P – the poll bit – obliges the gNB to send a status report straight back.

The wider counter is not decoration. Eighteen bits gives a 262144-value sequence space against 4096 for the 12-bit form used on signaling bearers, which is what a high-throughput bearer needs so its transmit window never wraps around data that is still unacknowledged.

[Frame 42] The first acknowledgment, 0.8 ms later. A STATUS PDU is RLC's only control message and it is 3 bytes long. ACK_SN=1 does not mean "SDU 1 arrived" — it means *"the next SDU I am still waiting for is number 1"*, so everything below 1, namely SN 0, is safely in. E1=0 says no NACK block follows — a NACK, or negative acknowledgment, is how a receiver names a specific sequence number it never got — so nothing is missing.

Note the ACK_SN field is itself 18 bits wide here: a STATUS PDU's format follows the entity's configured sequence-number length, so the acknowledgment is shaped by the same sn-FieldLength line that shaped frame 41.

Fix this in your head now: **there is not one NACK in this entire capture.** Every status on this diagram is a pure cumulative acknowledgment.

[Frame 43] The downlink has its own counter. The gNB sends *its* SN=0. That is not a repeat of frame 41 – an AM bearer is two independent transmitting entities, one per direction, each with its own sequence numbers, poll timer and retransmission buffer. Uplink SN 0 and downlink SN 0 are unrelated packets.

[Frame 44] Same acknowledgment, eighteen times slower. ACK_SN=1 confirms the downlink SN 0 of frame 43, but it takes 14.2 ms where the gNB answered in 0.8 ms. RLC is not the bottleneck: the gNB schedules its own downlink immediately, while the UE cannot transmit even 3 bytes until it is granted uplink airtime. Every uplink status on this diagram costs 11 to 20 ms for that reason.

[Frame 47] Uplink SN=1 , SI = all bytes, poll set. Traffic is still light enough that one SDU makes one PDU.

[Frame 48] ACK_SN=2 — uplink SN 0 and 1 delivered, so the transmitter can drop both from its retransmission buffer.

[Frame 49] Downlink SN=1 , poll set.

[Frame 50.1] Three RLC PDUs in one radio transmission.
The uplink buffer has filled, and MAC packs everything that fits into the single grant it was given. The STATUS PDU comes out first: ACK_SN=2 clears the downlink SN 0 and 1 and answers frame 49's poll.

Piggybacking control onto a data grant is the normal case, not an optimisation – RLC hands MAC whatever it has and MAC fills the transport block. The diagram splits the three PDUs into separate arrows so each can be read on its own.

[Frame 50.2] Uplink SN=2, a complete 64-byte SDU — and P is **not** set, the first data PDU on this bearer without a poll. More data is queued behind it, so RLC withholds the poll. This is the rule that governs the rest of the diagram, and it comes straight from the configuration in frame 41: with pollPDU at p32768 and pollByte at kB750, the counter-based poll triggers will effectively never fire, so a poll happens only when the transmit buffer is about to run dry (TS 38.322 §5.3.3.2).

[Frame 50.3] Uplink SN=3, SI = "first segment of an RLC SDU" (value 1), still no poll. A 1264-byte SDU starts here, and the grant has room for only 539 of its bytes after the 3-byte header. Segmentation is never a property of the data — it is a property of the grant that happened to be available.

[Frame 51] SN=3 continues: S1 = "neither the first nor last segment" (value 3), S0=539. The Segment Offset is a byte count from the start of the original SDU, and 539 is exactly where frame 50 stopped. The header is 5 bytes here – 3 for the 18-bit sequence-number fields plus 2 for S0, which a non-first segment must carry – so 619 bytes on the wire mean 614 bytes of payload, ending at offset 1153.

[Frame 52.1] SN=3 completes: SI = "last segment" (value 2), S0=1153. Wireshark reassembles 3 fragments totalling 1264 bytes, contributed as 539 + 614 + 111 – the segments tile the SDU with no gap and no overlap.

All three segments carry the same sequence number. The number belongs to the SDU; segmentation is described entirely by SI and SO. Still no poll, because as the next arrow shows there is more in the buffer.

[Frame 63.2] Uplink SN=5, poll set – piggybacked, and polled because the buffer is empty behind it.

[Frame 64] ACK_SN=6 — uplink SN 5 delivered.

[Frame 66] Uplink SN=6 , poll set.

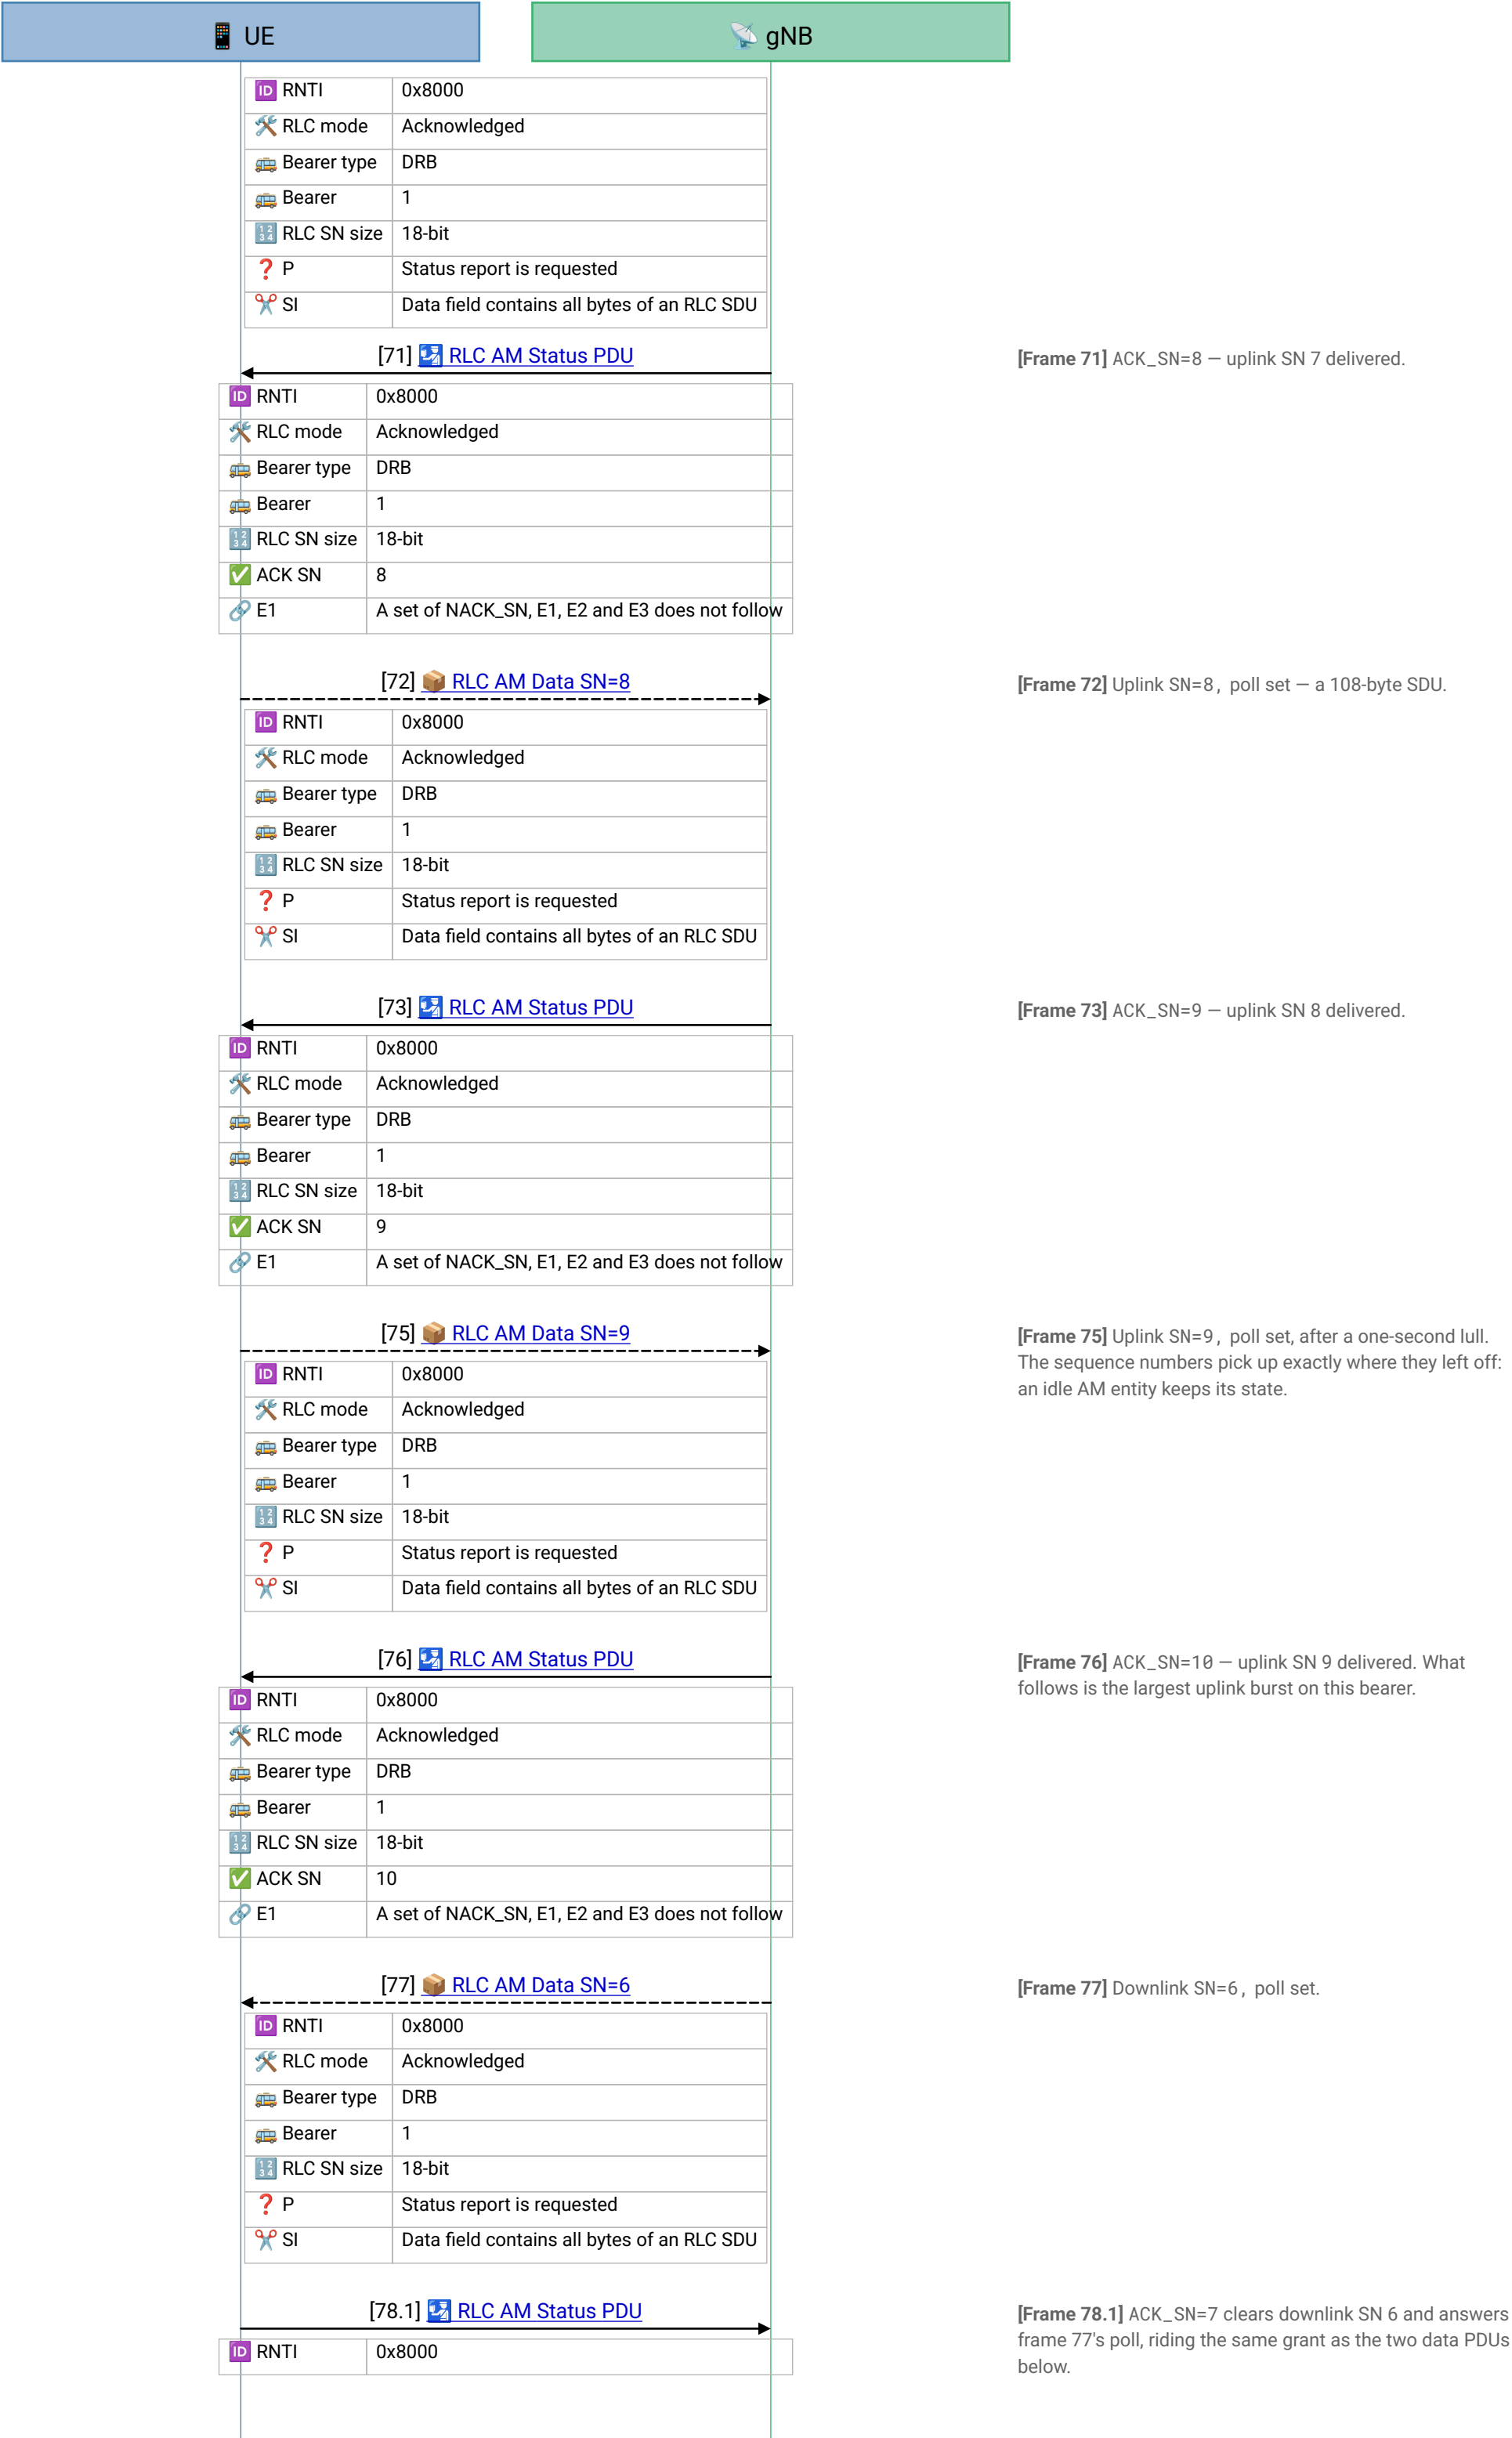

[Frame 67] ACK_SN=7 – uplink SN 6 delivered.

[Frame 68] Downlink SN=4, poll set.

[Frame 69] Downlink SN=5, poll set – one millisecond after frame 68. Two polls now sit unanswered, because the UE cannot reply until it is granted uplink airtime.

[Frame 70.1] Two polls, one answer. ACK_SN=6 covers downlink SN 0 through 5, so the polls of frames 68 and 69 are both satisfied by this single report. A STATUS PDU always describes the receiver's complete state up to ACK_SN, so a backlog of polls never means a backlog of statuses — which is exactly why RLC's control overhead stays flat as throughput rises.

[Frame 70.2] Uplink SN=7, poll set, sharing the transport block with the status above.

this one spread across three separate transport blocks rather than packed into shared ones, which changes nothing about how RLC describes it.

[Frame 96] SN=14 middle segment, SO=613, 614 bytes.

[Frame 97.1] SN=14 last segment, S0=1227, which is 613 + 614. Reassembly: 3 fragments, 1288 bytes, as 613 + 614 + 61. No poll yet – one more SDU is queued.

[Frame 97.2] Uplink SN=15, a complete SDU, and **this** is where the poll lands. The rule has now held for every burst on this bearer: P is set on the last PDU RLC hands to MAC before its buffer empties, wherever in a segmentation run that happens to fall.

[Frame 98] ACK_SN=16 — uplink SN 0 through 15 delivered, closing the frame 95 to 97 run.

[Frame 102] Downlink SN=9, poll set.

[Frame 105] ACK_SN=10 — downlink SN 9 delivered, 18.3 ms after the poll. The uplink status latency is still an order of magnitude above the downlink's; the scheduler sets that pace, not RLC.
